Abstract

Background: Acute hypoxemic respiratory failure is one of the leading causes of intensive care unit admission and is associated with high mortality. Noninvasive oxygenation strategies such as high-flow nasal cannula, standard oxygen therapy, and noninvasive ventilation (delivered by either face mask or helmet interface) are widely available interventions applied in these patients. It remains unclear which of these interventions are more effective in decreasing rates of invasive mechanical ventilation and mortality. The primary objective of this network meta-analysis is to summarize the evidence and compare the effect of noninvasive oxygenation strategies on mortality and need for invasive mechanical ventilation in patients with acute hypoxemic respiratory failure.

Methods: We will search key databases for randomized controlled trials assessing the effect of noninvasive oxygenation strategies in adult patients with acute hypoxemic respiratory failure. We will exclude studies in which the primary focus is either acute exacerbations of chronic obstructive pulmonary disease or cardiogenic pulmonary edema. The primary outcome will be all-cause mortality (longest available up to 90 days). The secondary outcomes will be receipt of invasive mechanical ventilation (longest available up to 30 days). We will assess the risk of bias for each of the outcomes using the Cochrane Risk of Bias Tool. Bayesian network meta-analyses will be conducted to obtain pooled estimates of head-to-head comparisons. We will report pairwise and network meta-analysis treatment effect estimates as risk ratios and 95% credible intervals. Subgroup analyses will be conducted examining key populations including immunocompromised hosts. Sensitivity analyses will be conducted by excluding those studies with high risk of bias and different etiologies of acute respiratory failure. We will assess certainty in effect estimates using GRADE methodology.

Discussion: This study will help to guide clinical decision-making when caring for adult patients with acute hypoxemic respiratory failure and improve our understanding of the limitations of the available literature assessing noninvasive oxygenation strategies in acute hypoxemic respiratory failure.

Systematic review registration: PROSPERO [CRD42019121755](https://www.crd42019121755)

Keywords: Hypoxia, Noninvasive ventilation, Oxygen, Oxygen inhalation therapy, Respiratory insufficiency

Background

Acute hypoxemic respiratory failure (AHRF) is among the leading causes of intensive care unit (ICU) admission in adult patients, [1], with around 40% of these patients receiving endotracheal intubation [2, 3]. Invasive mechanical ventilation (IMV) is associated with adverse events such as ventilator-associated pneumonia, ventilator-induced lung injury, and the potential for oversedation [4–6]. Avoiding unnecessary endotracheal intubation remains a major goal in the management of patients with AHRF [7–9]. Multiple noninvasive oxygenation strategies have been identified that might help avoid endotracheal intubation and decrease mortality, but it remains unclear which of these is most effective [9].

Previous studies have aimed to identify the optimal initial oxygenation strategy to avoid the receipt of invasive mechanical ventilation in adults with AHRF but have often produced conflicting results [10–14]. Classically, standard oxygen therapy (SOT) has been the conventional approach evaluated. Standard oxygen therapy provides low-flow oxygen (< 15 L/min) using different interfaces such as nasal prongs, Venturi system, and non-rebreather masks. In the early 2000s, noninvasive ventilation provided by a face mask (FM-NIV) was shown to be superior to SOT in two small single-center randomized controlled trials (RCT) [10, 11]. In 2015, a large RCT failed to show superiority of FM-NIV on the rates of endotracheal intubation and all-cause mortality compared to SOT in immunocompromised patients [12]. More recently, the use of high-flow nasal cannula (HFNC) gained interest and use among clinicians as an alternative method to provide noninvasive oxygenation [15–17]. A large 3-arm RCT recently compared the efficacy of HFNC, FM-NIV, and SOT in adults with AHRF [13]. Although this study did not show a benefit in the primary outcome (invasive mechanical ventilation at 28 days), HFNC was associated with decreased all-cause mortality at 90 days. Furthermore, a post hoc subgroup analysis showed that in patients with severe hypoxemia ($\text{PaO}_2\text{:FiO}_2 < 200$ mmHg) HFNC decreased the need of invasive ventilation when compared with the other two modalities. Notably, the highest mortality was seen among the FM-NIV treatment arm. This study started to raise concerns for potential harmful effects associated with FM-NIV, which were further supported by two large observational studies [18, 19]. Potential mechanisms of harm attributable to FM-NIV as compared to

HFNC include the poor tolerance of the face-mask interface, increased risk of patient-ventilator asynchrony, and the inability to limit tidal volumes leading to high transpulmonary pressures and ventilator- and patient-inflicted lung injury [20–22]. As a result, recent guidelines have expressed uncertainty regarding the use of FM-NIV for the treatment of de novo AHRF [7]. Interestingly, in a subsequent study comparing HFNC vs SOT among immunocompromised patients, there were no differences noted in rates of invasive mechanical ventilation or mortality [14].

The use of a helmet interface to provide NIV (H-NIV) poses an attractive alternative to provide both oxygenation and ventilation in AHRF, potentially with better patient tolerability, patient-ventilator interaction, and the ability to provide ventilation for longer periods of time [23]. The potential benefits of H-NIV compared to SOT and FM-NIV to decrease the risk of ETI has been supported by recent RCTs [24–27]. In an RCT study conducted in 2010, H-NIV was found to decrease mortality and need for invasive mechanical ventilation compared to SOT in patients with hematologic malignancy [26]. Helmet-NIV was also found to decrease rates of invasive mechanical ventilation and mortality in a more recent single-center RCT compared to FM-NIV [25]. There are a series of physiologic mechanisms that may explain these results—predominantly related to the helmet interface. The helmet interface may act to decrease air leaks when compared to the face mask interface. This may permit more effective delivery of higher levels of positive end-expiratory pressure potentially increasing alveolar recruitment and decreasing respiratory drive [2, 8, 22, 27]. Furthermore, patients with AHRF seem to have better tolerance for a helmet interface minimizing the time that the therapy requires interruption—something not uncommon for FM-NIV [25]. Interestingly, there are currently no available head to head comparisons of H-NIV and HFNC for relevant clinical outcomes such as mortality and need for invasive mechanical ventilation.

Determining the optimal strategy to decrease rates of endotracheal intubation in patients with AHRF is essential to minimize morbidity and mortality associated with the need for invasive mechanical ventilation. Although HFNC has become widely used, evidence is lacking regarding its effect as compared to standard oxygen, and there are no

head to head comparisons between HFNC and H-NIV. The limitations of the current evidence are clearly reflected in clinical practice, where there exists high variability among clinicians in the use of these four noninvasive oxygenation strategies for AHRF [8]. Furthermore, although previous systematic reviews and meta-analyses have explored the effectiveness of HFNC in patients with AHRF, these studies have often pooled control group data as “any other strategy,” failing to account for the important physiologic and clinical differences of these alternative interventions [28–30].

Network meta-analysis (NMA) is a strategy to summarize the evidence of clinical studies which include multiple treatments [31]. By incorporating estimates from direct comparisons and indirect comparisons, NMAs allow estimation of treatment effects where head to head comparisons are scarce and can decrease the imprecision in pooled treatment effects even when head to head comparisons exist [32]. To our knowledge, no previous NMAs have been conducted to compare the relative effectiveness of all available noninvasive oxygenation strategies among a general population of adult patients with AHRF.

The primary objective of this NMA is to assess the association between different noninvasive oxygenation strategies and all-cause mortality in adult patients with AHRF. The secondary objective is to assess the association between different noninvasive oxygenation strategies and the receipt of invasive mechanical ventilation in adult patients with AHRF.

Methods

This protocol has been written in accordance with the Preferred Reporting Items for Systematic Review and Meta-Analysis Protocols 2015 statement (PRISMA-P) and its extension for NMA [33, 34]. This protocol is also registered in the International Prospective Register of Systematic Reviews (PROSPERO, CRD42019121755).

Criteria for included studies

Participants and settings

We will include any studies that enrolled adult patients (18 years of age or older) with AHRF, defined by the new onset of clinical signs (tachypnea, increased work of breathing), radiologic signs (unilateral or bilateral chest x-ray opacities), and gas exchange alterations (different degrees of hypoxemia). We will consider studies including patients treated in the intensive care unit, intermediate care unit, medical wards, and emergency department. Studies primarily focused in the treatment of acute exacerbations of chronic obstructive pulmonary disease (AE-COPD) or congestive heart failure (CHF) will be excluded. Specifically, we will exclude such studies if 50% or more of the included population are patients with either AE-COPD or CHF, acknowledging

that a lower threshold will exclude too many studies in the field. Our pre-planned sensitivity analysis will specifically address this issue. The rationale for exclusion is based in the already shown superiority of noninvasive ventilation for these conditions. Furthermore, we will also exclude studies including patients after extubation for major thoracic surgery.

Interventions and comparators

All interventions considered in this review are noninvasive oxygenation strategies. HFNC oxygenation refers to oxygen delivered through a nasal cannula, at a FIO₂ up to 1.0 and a flow rate that can be as high as 60 l/min. NIV provides positive pressure ventilation that can be delivered with different modalities: continuous positive airway pressure, bi-level positive airway pressure, or pressure support ventilation. The interfaces used can be either a face mask (FM-NIV) or a helmet (H-NIV). Given the potential differences in reported outcomes, these interfaces will be considered as two different interventions in the network. SOT (low-flow systems) comprise traditional nasal cannula, Venturi system masks, or non-rebreather masks. All of these modalities can provide oxygen at low flow (< 15 l/min) with varying levels of FIO₂.

Outcomes measures

The primary outcome of this study will be all-cause mortality, defined as the longest available in the first 90 days after randomization. The secondary outcome will be receipt of invasive mechanical ventilation (longest available at 30 days). Given that the criteria for endotracheal intubation might vary between studies, we will collect information on whether decisions to intubate were based on pre-specified criteria or not.

Study design and publication types

We will include only randomized controlled trials focused on the treatment of acute hypoxemic respiratory failure if a combination of any of these interventions was assessed: HFNC, FM-NIV, H-NIV, and SOT.

Information sources and search strategy

The following seven electronic bibliographic databases will be searched using a comprehensive search strategy developed by an information specialist (MR): (1) *Ovid MEDLINE*, (2) *Ovid EMBASE*, (3) *PubMed (non-MEDLINE records only)*, (4) *Ovid EBM Reviews-Cochrane Central Register of Controlled Trials*, (5) *EBSCO CINAHL Complete*, (6) *Web of Science*, and (7) *LILACS*. We will also search [ClinicalTrials.gov](https://www.clinicaltrials.gov), *WHO International Clinical Trials Registry Platform*, and *International Standard Randomized Controlled Trial Number Registry* for all registered clinical trials and

randomized controlled trials. The search strategy will be structured according to the *Peer Reviewed Electronic Search Strategies (PRESS) 2015 Guidelines* [35] (refer to [Supplementary File](#) for full search strategy). We will use a validated search filter for randomized controlled trials from the *Cochrane Handbook for Systematic Reviews of Interventions Version 5.1.0, Section 6.4.11* [36] to screen Ovid MEDLINE, Ovid EMBASE, and PubMed. We will adapt a pre-tested search filter for randomized controlled trials from the *Scottish Intercollegiate Guidelines Network* [37] for EBSCO CINAHL Complete and Web of Science. No limits will be applied to language, publication year, gender or race. We will manage all references and duplicates using EndNote X8 citation management software.

Study selection

Two reviewers (BLF and FA) will screen independently the titles and abstracts retrieved from the search strategy and the additional sources in order to identify those meeting the mentioned eligibility criteria. Subsequently, we will obtain full texts of the articles meeting these pre-specified criteria and review again in a second stage. Any disagreement between the reviewers will be discussed and referred to final decision by a third investigator (LM, HW, DS).

Data extraction

The two reviewers (BLF and FA) will perform data extraction independently in a pre-piloted data extraction form created in Excel (Microsoft®). Any differences will be resolved by consensus or discussion with a third author (LM). Abstracted data will include study characteristics (trial design, size, and funding source), patients' characteristics (age, sex, etiology of AHRE, immunocompromised status, and the presence of severe AHRE (PaO₂:FIO₂ ratio < 200)), details of the interventions (location of application, duration of the exposure to each of the oxygenation strategy, type of noninvasive ventilation modality), outcome data for each endpoint of interest.

Risk of bias assessment

The risk of bias will be assessed independently using the tools specified in the *Cochrane Handbook for Systematic Reviews of Interventions for RCTs* [27–30]. The following aspects will be assessed: (1) random sequence generation (selection bias), (2) allocation concealment (selection bias), (3) blinding of participants and personnel (performance bias), (4) blinding of outcome assessment (detection bias), (5) incomplete outcome data, (6) selective reporting (reporting bias), and (7) other sources of bias.

Patient and public involvement

This research will be done without patient involvement. Patients will not be invited to comment on the protocol design nor consulted to develop patient-relevant outcomes.

Data synthesis and analysis

We will summarize the included studies based on study and patient characteristics, outcome measures, and risk of bias. We will perform a series of pairwise Bayesian meta-analyses with a random-effects model, followed by a network meta-analysis using a Bayesian framework to derive head-to-head treatment effect estimates comparing all interventions. Analyses will be based on Markov chain Monte Carlo methods using prior distributions for event rates derived from previous literature, minimally informative treatment effect estimates, and informative prior distributions for heterogeneity estimates derived from external evidence [38]. We will report pairwise and NMA treatment effect estimates as risk ratios (RR), estimating summary treatment effect estimates from the median and corresponding 95% credible intervals (CrIs) from the 2.5th and 97.5th percentile of the posterior distribution. We will also rank interventions according to their apparent effectiveness and will calculate the probability that interventions have risk reductions or increases greater compared to standard oxygen therapy. We will quantify heterogeneity in treatment effects between studies using the posterior distribution τ^2 . Inconsistency (incoherence) between direct and indirect comparisons will be estimated using the node-splitting approach contrasting estimates from both direct and indirect evidence [39, 40]. We will visually assess model convergence using the Brooks-Gelman-Rubin diagnostic, trace plots, and auto-correlation plots. We will assess the goodness-of-fit of our final models by comparing the mean residual deviance with the number of contributing data points, calculating the percentage of standardized node-based residuals within 1.96 of the standard normal distribution, and visually inspecting the distribution of residuals on Q-Q plots. We will perform all analyses in R v3.6 and OpenBUGS.

Assessment of publication bias

We will assess for the presence of publication bias by examining the comparison-adjusted funnel plot [41]. We will examine the shape of the funnel plot and assume that there is a risk of publication bias if its shape is asymmetrical. We will formally test for asymmetry in the funnel plot by performing the Harbord's test [42].

Subgroup analysis

Where information is available, we will assess for credible subgroup effects using a random-effects NMA meta-

regression Bayesian model to determine whether the estimated treatment effects are affected by the following factors: (1) severe AHRF (PaO₂:FIO₂ ratio < 200) vs less severe AHRF (PF ratio > 200), hypothesizing that HFNC is better than SOT for patients with severe AHRF, and (2) immunocompromised patients (hematologic malignancies, solid tumors with active chemotherapy, treatment with immunosuppressant drugs, and solid organ transplant recipients) vs non-immunocompromised patients, hypothesizing that NIV may be more effective in immunocompromised patients.

Sensitivity analysis

We will perform sensitivity analysis for the treatment effect estimates by excluding studies with high risk of bias in each of the assessed items. Furthermore, we will conduct a sensitivity analysis by excluding those studies that included any patients with AE-COPD or CHF, and with non-informative prior distributions for the heterogeneity parameters.

Grading of recommendations

We will rate the quality of each direct, indirect, and NMA estimates based on the four-step approach suggested by the Grading of Recommendations Assessment, Development and Evaluation (GRADE) Working Group [43]. The network effect estimates for each of the potential comparisons and every outcome, along with the GRADE rating for certainty in the evidence, will be depicted in a summary of findings table.

Discussion

In summary, this Bayesian network meta-analysis will provide a comprehensive summary of the direct and indirect evidence on the efficacy of different noninvasive oxygenation strategies to prevent mortality and the receipt of invasive mechanical ventilation in adult patients with acute hypoxemic respiratory failure. The current protocol was written in accordance with the Preferred Reporting Items for Systematic Review and Meta-Analysis Protocols 2015 statement (PRISMA-P) and its extension for NMA. This protocol is also registered in the International Prospective Register of Systematic Reviews (PROSPERO). The overall quality of the evidence will be assessed using the Grading of Recommendations Assessment Development and Evaluation (GRADE) approach.

We expect this study will help with clinical decision-making when caring for adult patients with AHRF. Furthermore, the systematic approach will improve our understanding of the limitations of the available literature to inform the treatment of patients with AHRF. Finally, we believe that our results will help identify predictive

enrichment strategies that may improve the design of future randomized controlled trials.

AHRF: Acute hypoxemic respiratory failure; ICU: Intensive care unit; IMV: Invasive mechanical ventilation; SOT: Standard oxygen therapy; FM-NIV: Face mask noninvasive ventilation; RCT: Randomized controlled trial; HFNC: High-flow nasal cannula; H-NIV: Helmet noninvasive ventilation; NMA: Network meta-analysis; AE-COPD: Acute exacerbation of chronic obstructive pulmonary disease; CHF: Congestive heart failure

Authors' contributions

BLF, FA, LM, HW, and DS conceived the study. LDS and NDF contributed with the clinical background and expertise. BR, RS, and BDC contributed with the analytical plan and the bias assessment approach. MR performed the literature search plan. BLF, FA, LM, and DS drafted the protocol. All authors revised the protocol and approved the final version. DS supervised the study.

Funding

Dr. Bruno Ferreiro is supported by a Vanier Canada Graduate Scholarship.

Availability of data and materials

Data sharing is not applicable to this article as no datasets were generated or analyzed during the current protocol.

Ethics approval and consent to participate

This study will not include individual patient data. Therefore, ethical approval will not be required to conduct this SR and NMA. We expect that the findings of this study will be disseminated through presentation in national and international conferences and publication in peer review journals.

Consent for publication

Not applicable.

Competing interests

The authors declare that they have no conflict of interest relevant to the contents of this manuscript.
